Chapter 1

Introduction

1.1 The importance of music analysis

The incredible growth of the Web over the last pair of decades has drastically changed many of our habits. One of the areas that have been highly affected by this fast-paced growth is our consumption of multimedia contents: the use of physically-stored content is seeing itself heavily reduced, as we are more and more getting used to the access of huge databases of multimedia content through the Web.

(it would be nice to cite [3] here to present the subject in a more elegant way) Music is one of these fields that have been revolutionized by this trend: the last decade has seen the rise of several Web services (iTunes, Spotify, Pandora, Google Music just to name a few) that offer their users an easy way to access their enormous catalogue of songs. Statistics show an increasing rate of annual growth for each of these services, in both the amount of users and of revenues: now they are among the most used ways of enjoying and discovering music.

However, the transition to this type of services has brought to some new problems. One of them relies on the vastness of these databases: given that users want to easily discover new music suitable to their tastes through intelligently created playlists, a way to reasonably pick songs and artists among the entire catalogue is needed.

This, among others, has been one reason of the rapid growth of **Music Information Retrieval** (MIR), an interdisciplinary research field whose subject is to provide new ways of finding information in music. Main techniques of describing music can be grouped into two categories:

- Metadata (literally *data describing data*), descriptors of music not directly retrieved from the audio signal but instead from external sources ¹
- Audio content descriptors, automatically computed from audio.

When it comes to choosing one method over the other, it becomes clear that both these categories of tools have their own pros and cons. Regarding metadata, major concerns arise from the questionable consistency of the descriptors among the entire catalogue catalogue of music, given that they may have been extracted from several sources. Other concerns also arise from how well they actually describe the audio track. On the other hand, audio content descriptors (especially the low-level ones) may have no musical meaning and therefore they could be hard to understand. Many efforts have been taken in order to improve the methods of information extraction of both these categories. In general, however, audio content descriptors are thought to be more flexible, since they can be easily and equally computed for any track. One advantage of this technique relies on the fact that these kind of descriptors could easily be computed not just for each kind of song, but also for any segment inside of it. This has for example been exploited by *Shazam*, a widely-used smartphone app for music identification that analyzes peaks in the frequency-time spectrum throughout all song length to build a very robust song identification system [1]. Another popular product that performs audio content analysis just for short segments of a song is The Infinite Jukebox², a web-application built upon Echonest library and written by Paul Lamere, that allows users to indefinitely listen to the same song, with the playback automatically jumping to points that sound very similar to the current one. The Infinite Jukebox can be considered an application of the so-called *creative-MIR* [6], an emerging area of activity inner to MIR whose subject is to exploit MIR techniques for creative purposes. Other relevant software that exploit Echonest library for similar purposes is Autocanonizer³ and Wub Machine⁴. However, there aren't many commercial or research-based software tools that exploit this kind of techniques for creative interaction or manipulation of audio tracks at the moment. Probably the most relevant commercial system is Harmonic Mixing Tool⁵, that performs audio content analysis on the user's music collection in order to allow a pleasant and harmonic fade when mixing between songs. More recently, the research-based software

¹There is a lack of agreement on the use of the term metadata, therefore its meaning could be different in other resources. For instance, it may be used to indicate all the data describing an audio file, including the ones derived from some computation on the audio signal itself.

AutoMashUpper has been developed with the intent of automating generating multi-song mashup⁶ while also allowing the user a control over the music generated [7]. WRITE MORE ABOUT AUTOMASH HERE

1.2 Phonos Project

Phonos project⁷ is an initiative of the **Music Technology Group** (Universitat Pompeu Fabra, Barcelona) in collaboration with **Phonos Foundation**. Phonos was founded in 1974 by J.M. Mestres Quadreny, Andres Lewin-Richter and Luis Callejo, and for many years it has been the only studio of electroacoustic music in Spain. Many of the electroacoustic musicians in Spain attended the courses of the composer Gabriel Brncic at Phonos. It became Phonos Foundation 1982 and in 1984 it was registered at the Generalitat de Catalunya. In 1994, an agreement of co-operation with Music Technology group was established, with the purpose of promoting cultural activities related to research in the music technology. In 2014, an exhibition at Museum de la Musica has been planned, with the purpose of celebrating the 40th anniversary of Phonos and showing many of the instruments used in the studio, while allowing visitors to listen to the music works produced there during all these years. Given the songs' average length and their complexity, a way for the visitors to quickly and nicely explore a catalogue of songs produced in these 40 years was needed.

FIGURE 1.1: Phonos Logo.

1.3 GiantSteps

GiantSteps⁸ is a STREP project coordinated by JCP-Consult SAS in France in collaboration with the MTG funded by the European Commission. The aim of this project is to create the "seven-league boots" for music production in the next decade and beyond,

⁶A mashup is a composition made of two or more different songs playing together.

⁷<http://phonos.upf.edu/>

⁸<http://www.giantsteps-project.eu/>

that is, exploiting the latest fields in the field of MIR to make computer music production easier for anyone. Indeed, despite the increasing amount of software and plugins for computer music creation, it's still considered very hard to master these instruments and producing songs⁹ because it requires not only musical knowledge but also familiarity with the tools (both software and hardware) that the artist decide to use, and whose way of usage may greatly vary between each other. The GiantSteps project targets three different directions:

- Developing **musical expert agents**, that could provide suggestions from sample to song level, while guiding users lacking inspiration, technical or musical knowledge
- Developing improved **interfaces**, implementing novel visualisation techniques that provide meaningful feedback to enable fast comprehensibility for novices and improved workflow for professionals.
- Developing **low complexity algorithms**, so that the technologies developed can be accessible through low cost portable devices.

Started on November 2013, GiantSteps will last 36 months and the institutions involved are:

- **Music Technology Group**, Universitat Pompeu Fabra, Barcelona, Spain
- **JCP-Consult SAS**, France
- **Johannes Kepler Universität Linz**, Austria
- **Red Bull Music Academy**, Germany
- **STEIM**, Amsterdam, Netherlands
- **Reactable Systems**, Barcelona, Spain
- **Native Instruments**, Germany

1.4 Purpose of this work

The purpose of this work is to develop a software to be used by visitors during the exhibition *Phonos, 40 anys de música electrònica a Barcelona* and that allows users to

⁹ "Computer music today is like piloting a jet with all the lights turned off." (S. Jordà). <http://vimeo.com/28963593>

FIGURE 1.2: GiantSteps Logo.

easily explore a medium-sized collection of music. This software is intended to exploit latest MIR findings to create a flow of music, composed of short segments of each song, concatenated in a way that the listener can barely realize of the hops between different songs. The application must also allow users to interact with it in order to have some control over the generation of the playlist; specifically, the user should be able to give a general direction to this flow (through some sliders or others GUI elements) in regards to some relevant music features, in a way that the change in the musical output can be perceived. The application developed is meant to be part of the GiantSteps project and therefore should follow the three guidelines explained in the previous page. In addition to this, given its future use on a public place, the application is required to be easy to use also for non-musicians, as many of the visitors of the exhibition could be.

1.5 Introduction to the problem of Playlist Generation

The problem of playlist generation has already been addressed by many popular music platforms, such as *Last.fm*¹⁰, *Pandora*¹¹ and *Musicoverly*¹². The main objective of such services is to help users find tracks or artists that are unknown to them and that they may like, providing *personalized radio playlists*. However, a playlist may be defined, in a broad way, just as a sequence of tracks [16] and therefore its use could be more general. For instance, a common use of the term playlist refers to the broadcasting radio playlists,

¹⁰<http://last.fm>¹¹<http://www.pandora.com>¹²<http://musicoverly.com>

i.e. playlists made by DJs in a radio stations and often involving popular tracks. We can therefore define the problem of playlist generation as follows [16]:

Given (1) a pool of tracks, (2) a background knowledge database, and (3) some target characteristics of the playlist, create a sequence of tracks fulfilling the target characteristics in the best possible way.

This task is made particularly challenging by the average size of the music database on which the generation of the playlist is needed: already, personal music libraries can be huge [17], hence the corresponding amount of information to be processed in order to generate the playlist leads to very heavy computational tasks. Depending on the need of the application, these tasks may also be performed offline, although a real-time user interaction should be supported in many cases in order to allow the user to have some control over this generation process (such as in the case study of this work). As we will see in Chapter 2, extracting information from an audio signal is not a trivial task and many algorithms have considerable time-complexity, and this may lead to very long computational times already for the analysis of small-sized catalogues. Playlist generation is a well-known problem inside MIR [18] [19], since this task can be considered as a retrieval task if its definition is limited to the selection of tracks satisfying a user query [16]. Other major topics of MIR also include extraction of features and similarity analysis, that can be seen as a basis for building a playlist generation system [20].

1.6 Structure of the dissertation

This dissertation is organized as follows:

- The first part will at first give an overview regarding music analysis techniques, explaining *metadata*, audio content analysis and the differences between them. Then, common techniques of music similarity computation will be explained.
- The second part will be about the methodology, explaining the different stages of the development, the problems faced and the techniques used. A presentation of the case study will introduce to an explanation of the reasons that lead to prefer the use of some techniques over others.
- Finally, experimental results will be shown, together with some ideas regarding future development of the application.

Part I

Background

Chapter 2

Music Analysis Techniques

The main subject of MIR regards the *extraction and inference of musically meaningful features, indexing of music* (through these features) and the development of *search and retrieval schemes* [2]. In other terms, the main target of MIR is to make all the music over the world easily accessible to the user [2]. During the last two decades, several approaches have been developed, which mainly differ in the music perception category of the features they deal with. These categories generally are: *music content*, *music context*, *user properties* and *user context* [4]. *Music content* deals with aspects that are directly inferred by the audio signal (such as melody, rhythmic structure, timbre) while *music context* refers to aspects that are not directly extracted from the signal but are strictly related to it (for example label[23], artist and genre information [24] [25], year of release [26], lyrics [27] and semantic labels). Regarding the user, the difference between *user context* and *user properties* lies on the stability of aspects of the user himself. The former deals with aspects that are subject to frequent changes (such as mood or social context), while the latter refers to aspects that may be considered constant or slowly changing, for instance his music taste or education [4].

In this chapter, we will focus on the differences between the categories *music content* and *music context*.

2.1 Metadata

By metadata we mean all the descriptors about a track that are not based on the *music content*. Therefore, they are not directly extracted from the audio signal but rather from external sources. They began to be deeply studied since the early 2000s, when first doubts about an upper threshold of the performance of audio content analysis systems arised [5]. Researchers then started exploring the possibility of performing retrieving

tasks on written data that is related to the artist or to the piece.

At first, the techniques were adapted from the Text-IR ones, but it was immediately clear that retrieving music is fairly more complex than retrieving text, because the music retrieved should also satisfy the musical taste of the user who performed the query.

The techniques used in this category may differ both in the sources used for retrieving data and in the way of computing a similarity score, and clearly the performance of a system using metadata for similarity computation is highly affected by both of these factors. Sources may include [12]:

- manual annotation: description provided by experts; they may be referred to genre, mood, instrumentation, artist relations.
- collaborative filtering data: data indirectly provided by users of web communities, in the form of user ratings or listening behaviour information.
- social tags: data directly provided by users of social network of music (such as *Last.fm*¹) or social games.
- information automatically mined from the Web. Sources in these cases may include web-pages related to music or microblogs (for instance the very popular Twitter).

The availability of some of them greatly depends on the size of the music collection under consideration; for instance, as manual expert annotations might be very accurate, they would be extremely costly and probably infeasible on large collections [8]. In contrast, collaborative filtering data may be the most studied technique, given that it may be applied to other different fields (such as movies or books recommendation) with just little changes. It is the predominant approach in the field of Recommender Systems (RS) [35] and is mainly focused on user ratings, generally leading to better results [11]. However, some concerns are related to this technique. First, collaborative filtering approaches have not been designed to be used for playlist generation, but mainly for recommending artists or music. Second, the availability of datasets for user ratings in the field of music is very limited compared to other fields, and research is often based on very small samples [36]. Regarding listening behaviour information, they might be inaccurate since they don't keep track of song durations and of the user activities while listening to music [38]. In addition, there's no way of collecting negative feedback (*dislikes*) through them and, more in general, listening to a specific song doesn't necessarily imply liking that song [12].

Sources are picked also in relation to the subject of the research or of the system, that may be for example a recommendation or a similarity computation system. At this point,

¹<http://last.fm>

it's important to highlight the difference between the two of them: a recommendation system not only has to find similar music, but has also to take into account the personal taste of the user, and therefore it's generally considered as a basic tool to produce recommendation [22]. In any case, the terms "similarity" and "recommendation" cannot be substituted, given that a good similarity computation system doesn't necessarily equate to a good recommendation system [37]. The computation of similarity may happen through a Vector Space Model (a technique adapted from the Text-IR), co-occurrence analysis or frequent-pattern mining. In the next subsections we will briefly show the characteristics and the performance of these techniques.

2.1.1 Vector Space Model

The main idea of this technique lies on building a bag-of-words representation ² of a retrieved document, and then computing a term weight vector for each document. It's a frequently used technique in Text-IR (and in Computer Vision) which can safely be used when retrieving web pages related to music, in an attempt of computing similarity. One of the first work in this field [39] provided an analysis of this kind on music-related web pages retrieved with the queries (to the *Google* search engine) "artist" **music review** and "artist" **genre style**, where words such as music and review were added to improve the chances of automatically retrieving webpages related to music.

2.1.2 Co-Occurrence Analysis

2.1.3 Frequent Pattern Mining

2.2 Audio Content Analysis

The main idea behind this kind of analysis is to directly extract useful information, through some algorithms (or library of algorithms), from the audio signal itself. The type of content information extracted may greatly vary in relation to the need of the research, but we can mainly distinguish four categories [12]:

- *timbral* information: related to the overall quality and color of the sound.

²A bag-of-words can be basically seen as an extension of a programming language "dictionary": it collects words (that sometimes may just be an abstraction of much more complex features, such as computer vision descriptors) from a document, and then computes the frequency with which each of them appears in the document. Two different documents are considered similar if they contain the same or similar words with a comparable frequency.

- *temporal* information: related to rhythmic aspects of the composition, such as tempo or length of measures.
- *tonal* information: directly linked to the frequency analysis of the signal and to the pitch. It can describe what notes are being played or the tonality of a given track.
- *inferred semantic* information: information inferred (usually through machine learning techniques) from the previous categories, in the attempt of giving a more defined and understandable shape to the data collected. This kind of information may include descriptors such as genre, valence or arousal.

Information extracted through this family of techniques may also be categorized in the following way:

- Low-level data: information that has no musical meaning and that, more in general, is not interpretable by humans. Examples of this kind of descriptors are Mel Frequency Cepstral Coefficients (MFCCs) and Zero Crossing Rate (ZCR).
- Mid-level data: information that has musical meaning but that is related to low-level music features. This kind of category mainly includes temporal and tonal descriptors.
- High-level data: corresponding to inferred semantic information.

Many of the studies conducted on the computation of music similarity through audio content descriptors have solely focused on low-level and timbral information, because this has been proved to bring alone to acceptable results with proper similarity measures [13]. However, more recent studies have shown some evidence of advantages in using high-level descriptors [14] [15] and, more in general, the most performant systems use data from all of these categories.

In the next sections, a more detailed look among most important descriptors will be given.

2.3 Conceptual Differences Between Metadata and Audio Content Information

The performance of content-based approaches is considerably lower [9]. It is challenging to try to make the so-called *semantic gap* smaller [10]

The advantage of relying on the audio signal over, say, expert annotations, is that the process is objective and can be automated to a large extent. However, extracting the features can be computationally costly [21]. Another limitation is that there might be features like the release date, the “freshness,” or popularity of a track, which can be relevant in the playlist generation process but that cannot be extracted from the audio signal [22].

When used in an automated process, data completeness and consistency are crucial. Another potential problem is that not all types of metadata are objective, and annotations regarding, for example, the mood or the genre of a track can be imprecise or inconsistent [28].

(speaking of tags) Although such annotations can be rich and diverse, the perception of music is again subjective and can even be influenced by the perception of other people [29]; tags only for popular songs [28]

When dealing with track ratings: grabbed from a wall posting on Facebook [30] or a tweet on twitter [31], 1-to-5 rating scales like on iTunes. Challenges: problem of data

sparsity (especially for the tracks from the long tail), a positivity bias (the phenomenon that most of the ratings are highly positive and negative feedback is rare [28]).

Chapter 3

Computing Music Similarity with Audio Content Descriptors

3.1 Literature Review

The coherence of the tracks is a typical quality criterion for playlists [32]. Therefore, selecting and ordering tracks based on their similarities is an obvious strategy to generate playlists. The core of any similarity-based approach is its distance function, which characterizes the closeness of two tracks. How the distance function is actually designed depends on the available data, which could include the raw audio signal along with the features that can be derived from it, but also metadata, such as the artists, the genres, playcounts, or ratings [Slaney and White 2007]. In many cases, a signature or model of each track is determined first, in which the distance function is then applied. Typical examples for such functions applied on more abstract models of a track's features are the earth-mover's distance [32], the Kullback-Leibler (KL) divergence [33], or the Euclidean distance [34].

See section 5.2 of [16] for a background on how to assess the quality of a playlist: user studies, log analysis, objective measures, comparison with handcrafted playlists
